# Self-employed mothers and the work-family conflict 

Jose Ignacio Gimenez-Nadal ${ }^{\text {a,* }}$, Jose Alberto Molina ${ }^{\text {a,b }}$ and Raquel Ortega ${ }^{\text {c }}$<br>${ }^{\text {a }}$ Faculty of Economics, Department of Economic Analysis, University of Zaragoza, C/Gran Via 2, 3rd floor, Zaragoza, 50005, Spain<br>${ }^{\mathrm{b}}$ Institute for the Study of Labor - IZA, Bonn, Germany<br>${ }^{\text {c }}$ Department of Business Administration, University of Zaragoza, C/Gran<br>Vía 2, Zaragoza, 50005, Spain

We analyse how self-employed and employed mothers allocate their time throughout the day in order to balance their work and family responsibilities. To that end, we use time diary information from Spain, a country with a low level of women's participation in the labour market (Spanish Time Use Survey (STUS), 2002-2003). We find that selfemployed mothers devote less time to market work, and more time to tertiary (e.g. sleeping, eating) and leisure activities, than employed mothers in a working day. We also find differences between employed and selfemployed mothers in the timing of market work, child care and housework throughout the day, and we find complementarities between the timing of market work of working mothers and the timing of child care of their male partners. Our results on timing are consistent with the hypothesis that self-employment stands as a possible way for mothers to have greater control over the timing of work (flexible hours), and that they may therefore be able to work odd shifts, when the spouse is available to care for the children.

Keywords: self-employment; market work; child care; timing
JEL Classification: C14; D13; J12; J13; J22

## I. Introduction

Recent decades have brought about a noticeable change in the role of women in the labour market. The female labour force participation rate in the US, as in Northern European countries, is approximately $70 \%$, significantly higher than in Southern European
countries, such as Spain, which has a participation rate of around $58 \%$ (OECD, 2005). These figures point to changes in social and gender roles (Layard, 2005) and indicate that roles taken by married/cohabiting women have changed during recent decades, with many such women having now become paid workers as well as homemakers.

[^0]However, most women continue to do more of the housework and parenting (Robinson and Godbey, 1997; Bianchi et al., 2000; Coltrane, 2000; Aliaga, 2006), with this creating an extra strain, the so-called 'double burden' or 'second shift' (Hochschild and Machung, 1989; Schor, 1991; Hochschild, 1997). ${ }^{1}$ Thus, women show discontent with the amount of free time available to them (Robinson and Godbey, 1997; Bittman and Wajcman, 2000; Mattingly and Bianchi, 2003; Sayer, 2005; Mattingly and Sayer, 2006), and the increased popularity of workplace flexibility programs and supportive work-family policies reflects the intensification of the conflict between working and household responsibilities usually associated with negative consequences for workers' health and workplace performance (Netemeyer et al., 1996; Kossek and Ozeki, 1999; Allen et al., 2000; Grzywacz and Bass, 2003; Byron, 2005; Mesmer-Margnus and Viswesvaran, 2005a, b).

Given these realities, one commonly-held view of women's motives to choose self-employment is a desire for greater flexibility, and the ability to spend more time caring for children (Presser, 1989; Connelly, 1992; Loscocoo, 1997; Caputo and Dolinsky, 1998; Boden, 1999; Hundley, 2000; Lombard, 2007; Arai, 2008). Within this framework, the objective of this article is to analyse whether self-employment stands as a possible way for mothers to have greater control over the hours they work (flexible hours), examining how self-employed and employed mothers deal with conflicting family and work pressures.
To that end, we use data from Spain, where labour markets remain highly regulated, with strict rules concerning the hiring and firing of workers, and the types of employment arrangements permitted. This contributes to the emergence of obstacles to leaving and re-entering the labour market, while becoming a parent and raising children, and results in women in Spain participating less in the labour market and having fewer children (Del Boca, 2002). Furthermore, child care services in Spain are typically inadequate and characterized by extreme rigidity in the number of weekly hours available. Only $2 \%$ of child care slots for children up to age 3 are publicly funded, which is the lowest percentage in Europe. Parental leave in Spain is granted to families rather than to individuals,
for a maximum of 36 weeks, unpaid, and offers no flexibility at work. ${ }^{2}$

We contribute to the existing US literature on the relationship between self-employment and the workfamily conflict by providing evidence for a European country, Spain, representing the Mediterranean rim. Although North American studies focusing on selfemployment have indicated that self-employed women find it easier to combine work and family responsibilities than employed women (Goffee and Scase, 1983; Scott, 1986; Kaplan, 1988; Buttner, 1993; DeMartino and Barbato, 2003; Lombard, 2007), little actual empirical work has been carried out in this area in the European context. Likewise, given previous evidence hypothesizing that self-employed mothers spend less time in the labour market and more time caring for their children than do employed mothers, we analyse whether self-employed mothers devote more time to child care activities than employed mothers. We also analyse whether the timing of activities for selfemployed mothers differs from that of employed mothers, allowing self-employed mothers to shift part of their working responsibilities to unusual hours, and to devote more time to child care activities during the mornings.

We find that self-employed mothers devote less time to market work and more time to tertiary (e.g. sleeping, eating) and leisure activities than employed mothers in a working day. This evidence is in line with Reynolds (2005) who finds that 'work-life conflict makes women want to decrease the number of hours they work whether the conflict originates at home or at work.' Given the desire to reduce the amount of work hours for mothers who are dealing with conflicting family and work pressures, self-employment allows for such a reduction.

Additionally, we find no difference in the amount of time devoted to child care activities between employed and self-employed mothers, which contrasts with the existing literature hypothesizing a positive relationship between self-employment and time devoted to child care by mothers (Connelly, 1992; Edwards and Field-Hendrey, 1996; Caputo and Dolinsky, 1998; Boden, 1999). We do find, however, that, compared to employed mothers, self-employed mothers devote more time to child care activities

[^1]during the mornings and afternoons, while they devote more time to market work activities during the evening (from 5 pm to 9 pm ). These results are consistent with the hypothesis that self-employment stands as a possible way for mothers to have greater control over the timing of their work (flexible hours) and, therefore, mothers are able to work odd shifts, when the spouse is available to care for their children.

## II. Data and Variables

We use the Spanish Time Use Survey (STUS) (2002-2003), where each household member over 9 years old fills in a time sheet, covering the 24 hours of a day, from 6 am to 6 am the following day. This dataset allows us to accurately compute the total effective hours devoted to different activities, and to analyse the timing of these activities to identify changes in the underlying 'time-profiles' throughout the day (for studies analysing the timing of activities, see Hamermesh $(1998,1999)$ and Fisher et al. (2007) for the US; Bonke et al. (2004) for Denmark; Hyytinen and Ruskanen (2007) for Finland).

The sample is restricted to include employed and self-employed working mothers of children under 18, living in a heterosexual relationship (married or cohabiting), with no other restrictions concerning the presence of other family member, health status, or rural/urban status. ${ }^{3}$ Additionally, we look at working days, defined as days where people devote at least 60 minutes to market work activities, excluding commuting. The time constraint is more likely to become binding during a working day, when people must devote time to their work responsibilities, and, hence, the work-family conflict is more likely on such days.

## Dependent variables

Since there are a large number of different activities, we need to devise some way to aggregate these activities into useful economic categories, and thus we have chosen the four main categories used by Burda et al. (2008): Market Work, Household Production, Tertiary Activities and Leisure.

Market Work refers to activities for which people are paid. Household Production refers to activities in
which we engage at home, using our own time and some purchased goods and have the common characteristic that we could pay someone to perform them for us, while we are not paid for performing them. The third group is Tertiary Activities, which refers to things that we cannot pay other people to do for us, but that we must do for ourselves, at least to some extent (e.g. sleeping, eating). Finally, Leisure includes all activities that we cannot pay someone else to do for us, and that we do not really have to do at all if we do not wish to. What distinguishes Leisure from other types of home activities is that one can function perfectly well, albeit not necessarily happily, with no leisure whatsoever. In other words, Leisure is not necessary for survival. ${ }^{4}$
Regarding these activities, while employed mothers may consider time spent with co-workers, colleagues and clients, other than while working, as Leisure, selfemployed mothers may consider such time as part of the job, since the success of their economic activities or business depends on their ability to win clients (networking). This may result in the self-employed considering some activities as Market Work, while the employed consider the same activities as Leisure. Thus, the potential difference in the time devoted to Market Work by both groups may be upwardly biased. We also find a downward bias in commuting time. Travel to/from work may make a difference in the time devoted to Market Work between employed and self-employed mothers, since the self-employed can be working at home and, therefore, we do not include commuting time in Market Work.
Additionally, Child Care poses a conceptual challenge (Aguiar and Hurst, 2007). It has been argued that Child Care differs from Housework in terms of the utility generated. For example, when asked to assess the satisfaction they receive from various activities, individuals consistently rank time spent playing with and reading to their children as being among the most enjoyable (Robinson and Godbey, 1997). Furthermore, individuals consistently report that general Child Care is more enjoyable than activities such as housework, grocery shopping, yard work, cleaning, doing dishes and laundry. Such survey evidence suggests that it may be appropriate to examine Child Care separately from other categories of time use, such as leisure and housework.

[^2]
## Explanatory variables

We control for age and age squared divided by 100 (Kalenkoski et al., 2005; Aguiar and Hurst, 2007), in order to account for the allocation of time over the life-cycle. For instance, we should expect an inverted U-shaped effect of age on Child Care activities, since the majority of Spanish women have children when in their early 30 s, and the time required for Child Care decreases as children grow older. ${ }^{5}$ We also consider the effects of family structure (Kalenkoski et al., 2005), controlling for the number of children in the household, breaking down children's age according to school cycles (Number of children 0-2, Number of children 3-5, Number of children 6-12, Number of children 13-17). We also control for the number of members in the family, since it is possible that the presence of grandparents (especially grandmothers) reduces the time devoted to Household Production and Child Care activities.

We control for whether mothers live in an urban or rural area (Kalenkoski et al., 2005). The availability of child care services, which may be more limited in rural areas, may condition the time allocation of mothers and they may find more difficulty combining work and family responsibilities, making self-employment a viable way to alleviate this conflict. Additionally, Kalenkoski et al. (2005) find that, if women have any health limitations, they devote less time to Market Work. For this reason, we control for the self-reported health status of the mothers ( 5 = very poor, $\ldots, 1=$ very good ).

We also control for the educational level of the mothers (Kalenkoski et al., 2005; Aguiar and Hurst, 2007). Aguiar and Hurst (2007) show a dispersion of Leisure favouring the less-educated, while Kalenkoski et al. (2005) find that highly-educated women devote more time to Market Work and Child Care. We use two dummy variables to control for university and secondary levels of education (the reference category is primary education). We also control for marital status (Kalenkoski et al., 2005), with the reference category being cohabiting (versus married).
Additionally, we need to control for the work characteristics of the mother. Hence, we control for part-time (self-reported) and self-employment (self-
reported) status, occupation and own hourly wage. First, we acknowledge that the part-time and selfemployment status are choice variables (e.g. Lombard (2007) finds that a woman is more likely to choose self-employment the greater her demand for flexibility), although we consider them to be exogenous variables, since we are interested in finding whether these choices affect the mothers' allocation of time. Second, we need to control for the occupation of the individual (type of work), since it could be that the number of hours devoted to Market Work, and the timing of these activities, is in fact a function of the type of work, rather than of an individual choice. ${ }^{6}$ Third, according to Altman (2001), whether labour supply increases or decreases, as a consequence of a change in real wages, depends on whether or not the substitution effect outweighs the income effect. But such a link is analytically suspect, since we do not know, a priori, the reasonable circumstances under which one effect should outweigh the other, nor the circumstances under which the elasticities of price and income effects can be expected to be large or small.

Thus, we use two dummies to control for the parttime ( $1=$ yes; $0=$ no) and self-employment status ( $1=$ yes; $0=$ no). For occupation, we have considered the 11 categories used in Hersh (2009). ${ }^{7}$ Finally, we include the (log) hourly wage rate to control for income and substitution effects. To compute the own wage rate, since income in the STUS is defined in intervals, we first assume an underlying normal distribution of the earnings variable, and apply interval regression techniques to compute the expected value (mean) of earnings in each of the earnings intervals. Once we obtain the expected value of earnings, we divide such earnings by the hours per week devoted to market work activities. To allow for nonlinear effects, we use the logarithm of wage rate.

## Descriptive evidence

Panel A in Table 1 shows means and SDs of the time use variables for employed and self-employed mothers of children under 18 in a working day.
${ }^{5}$ According to EUROSTAT, the mean age of women at first birth in 2002 was 30.77 years in Spain.
${ }^{6}$ For instance, if the self-employed mother is opening a new restaurant, she would be less likely to be flexible than a regular employee. Furthermore, the type of commitment required by so-called 'high-powered' jobs, such as law or medicine, may require a significant amount of up-front time in order to become established, so being self-employed may also predict working longer hours, less time spent with children and less flexibility. Thus, a comparison between the self-employed and the employed, without controlling for the type of job, may be misleading.
${ }^{7}$ We control for the following occupations: Management, business, financial; Professional and related; Healthcare support; Protective service; Food Preparation and serving related; Building and grounds cleaning and maintenance; Personal care and service; Sales and related; Office and administrative support; Natural resources, construction and maintenance; and Production, transportation and material moving.

Notes: ${ }^{\text {a }}$ SDs in parentheses.
${ }^{\mathrm{b}}$ Sample consists of nonretired/nonstudent partnered working mothers of children under 18 in the STUS (2002-2003).
${ }^{\text {c }}$ Time use variables are measured in minutes per day.
${ }^{\mathrm{d}}$ Column (4) shows the $p$-value of the differences, with a $p$-value lower than 0.05 meaning that the difference is statistically significant at the $5 \%$ level.

Although we find differences in the time devoted to their daily activities between employed and selfemployed mothers, most such differences are not statistically significant at the $5 \%$ level. We only find a statistically significant difference between employed and self-employed mothers in the amount of time devoted to Tertiary Activities, since self-employed mothers devote 16.93 more minutes per working day to Tertiary Activities, compared to employed mothers. This result is consistent with Hyytinen and Ruskanen (2007) who find that Finnish self-employed individuals get more sleep.

Panel B in Table 1 shows summary statistics of the explanatory variables in our sample. We find no statistically significant differences at the $5 \%$ level among employed and self-employed mothers in age, number of family members, health status, civic status and number of children. However, we do find statistically significant differences at the $5 \%$ level for other demographic characteristics. Spanish selfemployed mothers are less likely to live in urban areas than Spanish employed mothers ( $34.58 \%$ and $46.96 \%$, respectively), are less likely to have university education ( $24.34 \%$ and $38.38 \%$, respectively),
have a lower (log) wage rate ( 2.05 and 2.85 , respectively), and are less likely to work part-time ( $3.20 \%$ and $12.10 \%$, respectively). Regarding differences in occupations, compared to employed mothers, selfemployed mothers are more likely to work in 'Management, business, financial' and 'Natural resources, construction, maintenance', while those same mothers are less likely to work in 'Professional and related', 'Healthcare support', 'Protective services', 'Building and grounds cleaning and maintenance' and 'Office and administrative support'.

In summary, we find no statistically significant differences in the time devoted to Market Work, Child care, Household Production and Leisure, although we do find a statistically significant difference in Tertiary Activities, favouring the selfemployed mothers. However, in this analysis, we need to control for other demographic and household characteristics, such as the number and age of the children, the wage rate and occupation. For instance, Gimenez-Nadal and Sevilla-Sanz (2011) find that working mothers have leisure levels that are much lower than comparable working fathers or singles. Thus, such mothers may use self-employment as a way to reduce conflicting family and work pressures.

## III. Empirical Strategy and Results

## Empirical strategy

We condition the time allocation decisions of mothers on demographics. Thus, we estimate the following Ordinary Least Square (OLS) model for each time use category (Market Work, Household Production, Tertiary Activities, Leisure and Child Care): ${ }^{8}$

$$
\begin{align*}
& Y_{i}= \alpha+\gamma_{\text {Personal }} \text { Personal }_{i}+\gamma_{\text {family }} \text { Family }_{i} \\
&+\beta_{1} \text { Part-Time }_{i}+\beta_{2} \text { Self-Employed }_{i} \\
&+\beta_{3} \text { Occup }_{i}+\beta_{4} \text { Children } \text { Part-Time }_{i} \\
&+\beta_{5} \text { Children } * \text { Self-Employed }_{i}+\beta_{6} \text { Part } \\
&- \text { Time } \text { Self-Employed }  \tag{1}\\
& i
\end{align*}+\gamma_{\text {day }} \text { Day }_{i}+\xi_{i}
$$

where $Y_{i}$ is the time use category for individual ' $i$ '; Personal $_{i}$ is a vector of personal characteristics (age,
age squared, urban/rural, health status and civic status); Family ${ }_{i}$ is a vector of family characteristics (Number of children 0-2, Number of children 3-5, Number of children 6-12, Number of children 13-17, and Number of family members); Self_Employed ${ }_{i}$ is a 'dummy' variable to control for self-employment status; Part_Time $_{i}$ is a 'dummy' variable to control for part-time status; and $O_{\text {ccup }}^{i}$ is a vector of dummy variables that controls for occupation (type of work). Given previous evidence that self-employed women are more likely to have multiple children (Connelly, 1992; Caputo and Dolinsky, 1998; Boden, 1999), we include the interaction terms between the number and age of the children and being self-employed (and working part-time). Finally, we include an interaction term between 'self-employment' and 'working part-time', to avoid conflating part-time and selfemployment status. ${ }^{9}$

## Results

Table 2 shows the results of estimating an OLS regression for each dependent variable. We observe that Age and Age squared have statistically significant positive and negative associations, respectively, with the time devoted to Child Care, with these associations being statistically significant at the $1 \%$ level. Thus, age has an inverted $u$-shaped effect on Child Care, with the maximum being reached at the age of 37. This result is consistent with the life cycle of the family, in that, when children are young, the parents spend more time caring for them. Furthermore, Number of family members has a negative association with the time devoted to Child Care, since an additional adult member in the household reduces the time devoted to Child Care by the mother by 10.06 minutes in a working day, with this association being statistically significant at the $1 \%$ level.

Education has statistically significant effects on the time devoted to both Market Work and Household Production. University education has a statistically significant negative association with the time devoted to Household Production at the $5 \%$ level, with highly educated women devoting 25.98 fewer minutes to Household Production per working day than women with primary education. Furthermore, education has a statistically significant positive association with the
${ }^{8}$ We have also used several additional indicators to take advantage of contextual information included in the survey, such as the information about who else was present during an activity, and where the activity occurred. However, these additional ${ }_{9}$ indicators add little to the analysis (available upon request).
${ }^{9}$ We do not include interaction terms between the number of children and 'part-time*self-employed', since the low percentage of 'part-time self-employed' mothers leads to multicolinearity problems. We estimate OLS regressions for each time use category, and we obtain robust estimates using the population weights included in the survey. Day ${ }_{i t}$ is a variable scaling the day of the week when the survey took place (ref: Monday), and the omitted occupation is 'Medical professionals'. We do not show results for the day of the week and occupational dummies.

[^3]time devoted to Market Work, with highly and medium educated women devoting 24.96 (statistically significant at the $10 \%$ level) and 35.75 (statistically significant at the $1 \%$ level) more minutes to Market Work activities per working day, respectively.

The number of children has important effects on the allocation of time in a working day. In the case of full-time employed mothers (reference group), children under 13 have statistically significant positive associations with the time devoted to Child Care, with the highest effect being found for children under age 3, where an additional child increases the time devoted to Child Care by 87.40 minutes per day, and the lowest effect is found for the number of children between 6 and 12 years, where an additional child increases the time devoted to Child Care by 12.63 minutes per day. The number of children under 18 has statistically significant negative associations with the time devoted to Market Work, with the greatest effect being found for children under 3, while the number of children between 6 and 17 has statistically significant positive correlations with the time devoted to Household Production, with the greatest effect being found for children between 13 and 17 years old. All these associations are statistically significant at the $5 \%$ level.

Regarding the effects of children for part-time employed mothers, such effects are similar to the case of full-time employed mothers, the only statistically significant difference at the $5 \%$ level being that children under age 3 have a negative association with the time devoted to Household Production, decreasing the time devoted to these activities by 52.95 minutes per working day. In the case of full-time self-employed mothers, children have similar effects to the case of full-time employed mothers, with the difference being that the number of children between 6 and 12, and between 13 and 17 , have positive associations with the time devoted to Market Work and the number of children between 13 and 17 has a negative association with the time devoted to Leisure, with these associations being statistically significant at the 5\% level.

We now turn to the variables controlling for work status. On the one hand, compared to full-time employed mothers, working part-time has a statistically significant negative association with the time devoted to Market Work ( 150.52 fewer minutes per working day), while it has a statistically significant positive association with the time devoted to Household Production at the $1 \%$ level (113.21 more minutes per working day). Hence, we find a trade-off between the time devoted to Market Work and Household Production in a working day with parttime employment of mothers. On the other hand,
being full-time self-employed has a statistically significant negative association with the time devoted to Market Work (97.34 fewer minutes per working day), and statistically significant positive associations with the time devoted to Tertiary Activities (43.17 more minutes per working day) and Leisure (47.32 more minutes per working day), with these associations being statistically significant at the $5 \%$ level. Finally, compared to full-time employed mothers, being parttime self-employed has a statistically significant positive association with the time devoted to Tertiary Activities at the $5 \%$ level, with part-time self-employed mothers devoting 101.40 more minutes per day to Tertiary Activities than full-time employed mothers.

The analysis of aggregates of time use reveals that, when we control for observed heterogeneity, selfemployed mothers devote less time to Market Work, and more time to Tertiary Activities and Leisure than full-time employed mothers in a working day. These results are consistent with Hyytinen and Ruskanen (2007), who find that self-employed people get more sleep, and also with Biddle and Hamermesh (1990), who find that sleep is very much a choice variable. This evidence is also in line with Reynolds (2005), who finds that work-life conflict makes women want to decrease the number of hours they work whether the conflict originates at home or at work.' Given the desire to reduce the amount of work hours for mothers who are dealing with conflicting family and work pressures, self-employment appears to allow for such a reduction.

Furthermore, prior research has shown that the number of children in the home is positively related to the probability of self-employment, at least among women, as is the number of young children (Connelly, 1992; Caputo and Dolinsky, 1998; Boden, 1999). Similarly, the number of children at home is correlated with home-based work in the US (Edwards and Field-Hendrey, 1996). From this evidence, authors have inferred that self-employment is chosen in order to spend more time with the children.

None of the above studies answer directly, however, the question of whether self-employed individuals do indeed spend more time caring for their children. We find no evidence of this relationship between child care and self-employment. Although full-time self-employed mothers devote less time to Market Work activities than full-time employed mothers, we find no statistically significant association between self-employment and Child Care, which is in line with the findings of Hildebrand and Williams (2003).

Fig. 1. Timing of Market Work, Housework, Child Care and Leisure, mothers ${ }^{\text {a,b,c }}$
Notes: ${ }^{\text {a }}$ This figure plots the coefficients of self-employment dummy variables from regressions of timing of activities on age, day-of-week, family composition, mother's occupation and spouse's working controls.

${ }^{\text {c }}$ Each value represents timing-deviations from the employed mothers, conditional on demographics.

## IV. Self-Employment and Child Care

One of the arguments for the hypothesized relationship between self-employment and child care is that an individual in self-employment is perceived as having greater control over the timing of work (flexible hours), so the self-employed mother may be able to work during school hours, after the children have gone to bed, at odd shifts or parttime, when a spouse or another family member is available to care for the children. In such a case, we would observe a different timing in Child Care and Household Production, given that self-employed mothers with children are able to devote time to these activities at times when they otherwise could not, if they were working for a firm. Thus, we now analyse the timing of such activities throughout a working day, comparing employed and self-employed mothers.

For this analysis, we follow Hamermesh (1999) and we construct the series $T_{i t}$ where ' $i$ ' refers to the individual, and ' $t$ ' refers to the time band of the day. We divide the 24 hours of the working day into 24 time bands ( $t=1,2,3, \ldots, 24$ ), and we compute the amount of time devoted to the reference activity
(Market Work, Child Care, ...) in each time band ' $t$ '. We estimate the following OLS model for each time band:

$$
\begin{align*}
T_{i t}= & \alpha+\gamma_{\text {age } \text { Age }_{i}+}+\gamma_{\text {educ }} \text { Educ }_{i}+\gamma_{\text {family }} \text { Family }_{i} \\
& +\beta_{1} T_{i}+\beta_{2} \text { Self_Employed }_{i}+\beta_{3} \text { Occup }_{i} \\
& +\beta_{4} \text { Partner }_{i}+\gamma_{\text {day }} \text { Day }_{i}+\xi_{i t} \tag{2}
\end{align*}
$$

where $\mathrm{Age}_{i}$ controls for the age of the individual ' $i$ ' (and its square), $E d u c_{i}$ controls for education (ref.: primary education), Family $_{i}$ is a vector of family characteristics (Number of children 0-2, Number of children 3-5, Number of children 6-12, and Number of family members, married), $T_{i}$ is the total amount of time devoted to the reference activity for the individual ' $i$ ', Self_Employed $_{i}$ indicates whether the person is self-employed or not, Occup $_{i}$ controls for the occupation of the individual, Parther $_{i}$ is a vector of partner's work characteristics (partner is in a working day, and partner is self-employed), and $D a y_{i}$ is a vector scaling the day of the week (ref.: Monday). ${ }^{10}$
Figure 1 shows (see Table A1 in the Appendix for details) the estimated coefficients of the self-employment dummy variables on the timing regressions for Market Work, Household Production, Child Care and

[^4]Aggregated Housework (Household Production plus Child Care). First, we observe that there are statistically significant negative associations between being self-employed and the timing of Market Work, Household Production and Child Care from 6 am to 11 am , from 6 am to 7 am , and from 6 am to 8 am , respectively. At the same time, we find statistically significant positive associations between being selfemployed and Household Production and Child Care from 7 am to 11 am , and from 9 am to 12 am , respectively. Second, we find that being self-employed has statistically significant negative associations with Market Work from 1 pm to 3 pm , while it has significant positive associations with Household Production and Child Care in the same period. Third, being self-employed has statistically significant positive associations with Market Work from 5 pm to 9 pm , while it has statistically significant negative associations with both Household Production and Child Care from 5 pm to 7 pm .

Thus, we find that, compared to employed mothers, self-employed mothers devote 11.40 and 9.26 percentage points more of their time to Child care ( 6.36 more minutes out of 55.77 minutes, see Table 1) and Household Production (19.30 more minutes out of 208.48 minutes, see Table 1), respectively, in the period from 8 am to 3 pm . Additionally, we find that self-employed mothers devote less time to Market Work in the morning and afternoon (e.g. from 8 am to 3 pm ) compared to employed mothers, since they devote 10.54 percentage points less time to these activities ( 41.97 fewer minutes out of 398.27 minutes). Second, compared to employed mothers, we find that self-employed mothers devote 8.75 and 5.99 percentage points less of their time to Child care and Household Production in the evening (e.g. from 5 pm to 9 pm ), respectively, while self-employed mothers devote 11.23 percentage points more time to Market Work in the evening compared to employed mothers.
These results are consistent with the hypothesized relationship between self-employment and child care, that self-employed mothers are perceived as having greater control over the timing of work (flexible hours), so they may devote more time to the children in the mornings and afternoons, and they more easily work odd shifts, when a spouse or other family member is available to care for the children. Hyytinen and Ruskanen (2007) also find that the self-employed with younger children are more likely to work after 5 pm , when the majority of communal day-care centres close. Additionally, in the US, Stewart and Allard (2008) find that part-time employment allows mothers to spend more time with their children
during the mornings and afternoons, compared to full-time employment.

Given the hypothesized relationship between child care and self-employment, that self-employed mothers may more easily work odd shifts, when a spouse or other family member is available to care for the children, we now analyse the correlations between the timing of Child Care for men and the timing of Market Work of their employed spouses. To that end, we regress, for each time band, the proportion of time devoted to Child Care by men in the reference time band, conditioned on whether their female partners devoted time to Market Work (1) or not (0) during the same time band. For instance, considering the first time band of the day ( 12 pm to 1 am ), we estimate the probability (in percentage points) of devoting time to Child Care by men, conditioned on own demographics, family characteristics, total own time devoted to Child Care, own self-employment status and whether the wife is devoting any time to Market Work (1) or not (0) in this time band.

Figure 2 shows (see Table A2 in the Appendix for details) the associations between Child Care of men, and Market Work of their female partners. We find statistically significant positive associations from 7 am to 10 am , from 2 pm to 3 pm , and from 5 pm to 7 pm , with these associations being statistically significant at the $5 \%$ level. Thus, we find that, if the mother is devoting time to Market Work activities, the spouses of such working mothers are 4.90, 7.30, $2.00,3.10,4.30,3.20$ and 3.70 percentage points more likely to be devoting time to Child Care from 7 am to $8 \mathrm{am}, 8 \mathrm{am}$ to $9 \mathrm{am}, 9 \mathrm{am}$ to $10 \mathrm{am}, 2 \mathrm{pm}$ to 3 pm , 5 pm to $6 \mathrm{pm}, 6 \mathrm{pm}$ to 7 pm and 7 pm to 8 pm , respectively. Thus, we find complementarities between the time devoted to child care activities by men and the time devoted to market work activities by their spouses, since men devote more time to child care activities, if their spouses are working, than if their spouses are not, in most of the hours in the middle of the day.

Given such positive correlations, and since we find that, compared to employed mothers, self-employed mothers devote less time to market work activities from 8 am to 11 am and from 1 pm to 3 pm , and more time from 5 pm to 9 pm , we interpret these results as indicating that the spouses of self-employed mothers are more likely to devote time to child care activities from 5 pm to 7 pm , and less likely to do so from 8 am to 11 am and from 1 pm to 3 pm , compared to the spouses of employed mothers.

Thus, our results on timing support the hypothesized relationship between child care activities and self-employment. Mothers may choose selfemployment as a way to have greater control over

Fig. 2. Correlations between Market Work of mothers and Child Care of fathers ${ }^{\mathbf{a}, \mathrm{b}, \mathrm{c}, \mathrm{d}}$
Notes: ${ }^{\text {a }}$ This figure plots the coefficients of women's participation in Market Work activities ( $1=\mathrm{yes} ; 0=\mathrm{no}$ ) on men's percentage of time devoted to Child Care in each time band, conditioned on age, day-of-week, family composition, father's occupation and women's working characteristics.
${ }^{\mathrm{b}}$ Sample consists of nonretired/nonstudent fathers in couple with working mothers of children under 18 in the STUS (2002-2003).
${ }^{\text {c }}$ Each value represents correlations with the time devoted to Market Work activities by the wife, conditional on demographics.
${ }^{\mathrm{d}}$ Coefficients are multiplied by 100 .
the timing of work, so that the self-employed mother may be able to work at odd shifts, when the spouse is available to care for the children.

## V. Conclusions

This article deals with an important subject for policy decision-making, that is, how working conditions and work status interact with family responsibilities, especially with the time devoted to child care. We focus on self-employment as a possible way for mothers to have greater control over their allocation of time, using time diary data from the STUS 2002-2003.

Despite differences in the time devoted to Market Work, Tertiary Activities and Leisure between employed and self-employed mothers in a working day, we find no support for the hypothesis that selfemployed mothers spend more time caring for children than do employed mothers. However, we do find that self-employed mothers devote more time to Child Care and less time to Market Work during the morning and afternoon, and less time to Child Care and more time to Market Work during the evening, compared to employed mothers. We also find
complementarities between the time devoted to Child Care and Market Work by the members of the couple.
These differences in the timing of activities between employed and self-employed mothers, together with the complementarities between the time allocations of both members of the couple, are consistent with the hypothesis that self-employed mothers have greater control over the timing of work compared to employed mothers, since they are able to shift part of their market work responsibilities to the evening, when the spouse is available to care for the children. Given these differences, self-employment appears to be one significant strategy to improve the balance between work and family responsibilities. These findings are in accordance with the EU employment agenda for 2010, established in Lisbon in 2000, where one target was increasing female labour participation rates to more than $60 \%$ by 2010 , with a special emphasis on promoting entrepreneurship and selfemployment.
Furthermore, since working women with children face a 'double burden' (Gimenez-Nadal and SevillaSanz, 2011), public policies aimed at a more egalitarian distribution of nonmarket work by gender (e.g. Noonan, 2004) will help women to reduce levels of
stress, and to have more time to devote to other activities, such as leisure and personal care.

Notes: ${ }^{\text {a }}$ Robust SEs in parentheses.
${ }^{\mathrm{b}}$ Sample consists of fathers in couple with working mothers of children under 18 in the STUS (2002-2003). ${ }_{\mathrm{d} *}^{C}$ Child Care is measured in percentage points (e.g. proportion of Child Care in each time band).

[^0]:    *Corresponding author. E-mail: ngimenez@unizar.es

[^1]:    ${ }^{1}$ For instance, by the end of the 1990s, men in some Organization for Economic Co-operation and Development (OECD) countries devoted 3.29 hours per day to household production activities (housework plus child care), whereas women devoted 6.04 hours per day to such activities (Gauthier et al., 2004). Poortman and van der Lippe (2009) show that women have more favourable attitudes toward cleaning, cooking and child care than do men, a finding associated with women's greater contribution to household labour.
    ${ }^{2}$ The Spanish institutional context has improved somewhat in recent years, with the implementation of certain family-friendly policies and, although the portion of Gross Domestic Product (GDP) devoted by the government to gender equality policies has increased from $0.5 \%$ in 1998 to $1.1 \%$ in 2005, this is still the lowest in the EU (EUROSTAT). Such policies include the 'baby-check' ( $€ 2500$ ), and the Spanish law 'Ley para la igualdad efectiva de hombres y mujeres 2007/3'.

[^2]:    ${ }^{3}$ Despite the inherent diversity of the term 'self-employed', we use the generally accepted meaning, which refers to those individuals who are either entrepreneurs with no employees, or independent workers, since our data set does not allow us to distinguish between these two categories. Self-employed women can also define themselves as working part-time
    ${ }^{4}$ All these activities are measured as primary activities. Väisanen (2006) shows that the amount of time reported as secondary activity in the STUS is 82 minutes (out of 1440 minutes per day), the lowest among UK, Finland, France, Germany, Italy, Norway and Sweden, which makes the inclusion of secondary activities in the analysis not relevant.

[^3]:    Notes: ${ }^{\text {a }}$ Robust SEs in parentheses.
    ${ }^{\mathrm{b}}$ Sample consists of nonretired/nonstudent partnered working mothers of children under 18 in the STUS (2002-2003).
    ${ }^{\text {c }}$ Time use variables are measured in minutes per day.
    *, ** and ${ }^{* * *}$ denote significance at the 10,5 and $1 \%$ levels, respectively.

[^4]:    ${ }^{10}$ Since we find differences in the amount of time devoted to Market Work, Tertiary Activities and Leisure between employed and self-employed mothers, we need to control for such differences in our timing regressions, so we include the total time devoted to each activity. Controlling for whether the husband/partner is in a working day or not is also important, since the fact that the husband/partner is in a working day may require the mother to devote more time to Child Care, and less time to Market Work during the morning, than when the husband/partner does not have to work.
